NeuralSAT: A High-Performance Verification Tool for Deep Neural Networks

Hai Duong¹, ThanhVu Nguyen¹, and Matthew B. Dwyer²

¹ George Mason University, USA ² University of Virginia, USA

Abstract. Deep Neural Networks (DNNs) are increasingly deployed in critical applications, where ensuring their safety and robustness is paramount. We present NeuralSAT, a high-performance DNN verification tool that uses the DPLL(T) framework and supports a wide-range of network architectures and activation functions. Since its debut in VNN-COMP'23, in which it achieved the New Participant Award and ranked 4th overall, NeuralSAT has advanced significantly, achieving second place in VNN-COMP'24. This paper presents and evaluates the latest development of NeuralSAT, focusing on the versatility, ease of use, and competitive performance of the tool. NeuralSAT is available at: https://github.com/dynaroars/neuralsat.

Keywords: DNN Verification · Satisfiability Solving · VNN-COMP

1 Introduction

Deep Neural Networks (DNNs) have emerged as an effective approach for tackling challenging real-world problems. However, just like traditional software, DNNs can have "bugs", e.g., producing unexpected results on inputs that are different from those in training data, and be attacked, e.g., small perturbations to the inputs by a malicious adversary or even sensor imperfections can result in misclassification [20,36,33,35,13]. These issues naturally raise the question of how DNNs should be tested, validated, and ultimately *verified* to meet the requirements of relevant robustness or safety standards [12].

To address this question, researchers have developed a wide variety of algorithmic techniques and supporting tools to verify DNNs (§5). As a result, DNN verification has become a vibrant research area, and the community has created the annual DNN verification competition (VNN-COMP) to compare different approaches, showcase the latest advances, and help shape future directions of the field [5]. The first VNN-COMP was established in 2020, and the latest iteration of the competition, VNN-COMP'24, was held with CAV in 2024.

Unlike research papers, which often focus on theoretical contributions and has a smaller evaluation scale, VNN-COMP evaluates tools based on their practical performance on a wide range of benchmarks and properties and thus attracts the state-of-the-art in the field including: $\alpha\beta$ -CROWN, Marabou (successor of Reluplex), nnenum, and MN-BaB (successor of ERAN). Among these tools,

 $\alpha\beta$ -CROWN has been the most successful, winning the competitions four consecutive times from VNN-COMP'21 to VNN-COMP'24.

In 2023, we introduced the NeuralSAT₂₃³ verification tool in VNN-COMP'23, where it ranked 4th overall and received the New Participation award (and also won the "TLL Verify Bench" benchmark category). All versions of NeuralSAT uses a DPLL(T) approach with conflict-clause learning capability to handle difficult problems. We introduced several major improvements to NeuralSAT such as parallel DPLL(T) and neuron stabilization optimization [9] to define NeuralSAT₂₄, that demonstrated competitive performance with $\alpha\beta$ -CROWN on fully-connected networks. Further extensions supported a much larger set of network layer and activation function types and this NeuralSAT₂₄ participated in VNN-COMP'24, where it ranked 2nd overall behind $\alpha\beta$ -CROWN.

In this paper, we describe the latest version of NeuralSAT, which includes further extensions to optimize verification for more complex DNNs; the paper also reports on the extensions in NeuralSAT₂₄ that have not been previously reported. We focus on features and engineering optimizations in NeuralSAT that are essential for creating a high-performance tool. We evaluate NeuralSAT in comparison to both NeuralSAT₂₄ and the latest versions $\alpha\beta$ -CROWN, and we illustrate how NeuralSAT facilitates ease of use by avoiding the complexities parameter tuning necessary in other verifiers.

Users of NeuralSAT. We designed NeuralSAT for (i) researchers who want to experiment with DNN verification techniques, and (ii) practitioners who want to verify their networks. For the first type of users, the DPLL(T) framework, which is carefully designed to be modular and extensible, serves as a foundation for incorporating additional algorithmic techniques from the broader SMT and DNN reasoning literature. For the second type of users, NeuralSAT works out of the box and supports various types of network architecture with minimal configuration and tuning. Our goal is to create a high-performance yet easy-touse DNN verification tool that enables practitioners to employ state-of-the-art DNN reasoning techniques.

2 Background and Overview

2.1 The DNN verification problem

Deep Neural Network (DNN) A deep neural network consists of an input layer, multiple hidden layers, and an output layer. Each layer contains neurons connected to neurons in previous layers via predefined weights obtained through training with data. A fully-connected (FC) layer is a layer where each neuron is connected to every neuron in the previous layer.

 $^{^3}$ We use subscripts to distinguish previous versions of <code>NeuralSAT</code> from the version discussed in this paper.

The output of a DNN is computed by iteratively calculating the values of neurons in each layer. Neurons in the input layer receive the input data. Neurons in the hidden layers compute their values through an *affine transformation* followed by an *activation function*, like the popular Rectified Linear Unit (*ReLU*) activation. For ReLU activation, the value of a hidden neuron y is given by $ReLU(w_1v_1 + \ldots + w_nv_n + b)$, where b is the bias parameter for y, w_i, \ldots, w_n are the weights of y, v_1, \ldots, v_n are the neuron values from the preceding layer, $w_1v_1 + \cdots + w_nv_n + b$ represents the affine transformation, and $ReLU(x) = \max(x, 0)$ defines the ReLU activation. A ReLU-activated neuron is *active*, if its input value is greater than zero, or *inactive*, otherwise.

DNN Verification Given a DNN N and a property ϕ , the DNN verification problem asks if ϕ is a valid property of N. Typically, ϕ is a formula of the form $\phi_{in} \Rightarrow \phi_{out}$, where ϕ_{in} is a property over the inputs of N and ϕ_{out} is a property over the outputs of N.

Modern techniques often treat the DNN verification as a *satisfiability* problem. More specifically, given a formula α representing the ReLU-based DNN Nand the formulae $\phi_{in} \Rightarrow \phi_{out}$ representing the property to be proved, a DNN verifier checks the satisfiability of the formula

$$\alpha \wedge \phi_{in} \wedge \phi_{out}.\tag{1}$$

The verifier returns unsat if Eq. 1 is unsatisfiable, indicating that ϕ is a valid property of N, and sat otherwise, indicating the ϕ is not a valid property of N.

2.2 Overview of NeuralSAT

Fig. 1 gives an overview of NeuralSAT, which is modeled after the DPLL(T) framework in SMT solving [6,15]. NeuralSAT consists of standard DPLL components (non-shaded) and a theory or T-solver (shaded) dedicated for DNN reasoning.

DPLL search NeuralSAT treats DNN verification as a search for an activation pattern, represented as an assignment σ which maps truth values to the variables representing the activation status of neurons (BooleanAbstraction). In the beginning σ is empty, and NeuralSAT uses decision heuristics to select unassigned variables (Select) and assigns truth values⁴ to them (Decide). After each

assignment, NeuralSAT infers additional assignments caused by the current assignment through Boolean constraint propagation(BCP). Next, it invokes the Tsolver (Deduce) to check the feasibility of the current assignment in σ . If it is feasible, NeuralSAT continues to search for new assignments. Otherwise, NeuralSAT

⁴ As described later, NeuralSAT uses a parallel DPLL and thus will explore both branches of the decision.

detects a conflict, and it learns clauses to remember and backtracks to a previous assignment (Analyze-Conflict).

This process repeats until NeuralSAT can no longer backtrack, at which point it returns unsat, indicating the DNN has the property. Otherwise, it finds a complete assignment for all Boolean variables (i.e., a satisfying activation pattern), and returns sat. The user can query for a counterexample input in the case of sat.

If the NeuralSAT search falls into a local optima, it will restart the search by clearing all assignments that have been made. NeuralSAT retains learned conflict clauses learned, to avoid reaching the same state in the subsequent search.

NeuralSAT-specific Components NeuralSAT follows the standard DPLL algorithm, but includes several components specific for DNN reasoning [9].

T-Solver To check that current assignments in σ is feasible with the the formula in Eq. 1, the T-solver uses LP solving and polytope abstraction [11,32] to compute neuron bounds from the given precondition and σ , and checks the bounds are feasible with respect to the specified post-condition. Using LP solving and abstraction is standard in modern DNN verification tools [21,32,27,3]. However, the T-solver also implements *neuron stabilization* by creating and solving custom MILP constraints to determine if a neuron is stable (i.e., it is always active or inactive). If a neuron is stable, the T-solver does not need to guess its activation status, and thus reduces the search space.

Parallel DPLL NeuralSAT leverages multiprocessing to parallelize its DPLL search. When assigning values to variables, NeuralSAT considers both options (active or inactive) for each variable, and then splits the search space into two disjoint subspaces and processes them in parallel. When a conflict is detected in one subspace, NeuralSAT prunes that subspace and continues the search in the remaining subspaces. This parallelism not only speeds up the process but also facilitates information exchange such as learned clauses among search subspaces.

3 Implemented Features and Optimizations

From our experience evaluating tools and participating in competitions, we found that the novelty described in research papers often does not translate to competitive performance or practical usability. Instead, the implementation details, such as being versatile, easy to use, and employing "engineering" optimizations to improve performance matter perhaps just as much. Tab. 1 shows the features of NeuralSAT, many of which are often overlooked in research papers (e.g., absent in [9]) but are critical for building a long-term and high-performance tool.

Versatility The work in [9] focused on ReLU-based and fully-connected networks. NeuralSAT has since been extended to support a wide range of network architectures and activation functions. Currently, NeuralSAT works with fully connected

Feature	Supported			
Network Type	Acyclic computation graphs, e.g., Feed-forward, Residual			
Layer Type	FC, CNN, MaxPool, BatchNorm, Softmax			
Activation Function	ReLU, Sigmoid, Tanh, Sign, Exp			
Abstract Domain	Polytope, Interval			
Search Algorithm	Parallel $DPLL(T)$			
Hardware	Multi-core CPU, GPU			
Optimization	Adv. Attacks, Input splitting, Large Output Opt., MILP solving			
Property	Robustness, Safety			
Input	Pytorch, ONNX, VNN-LIB			
Output	(sat, unsat, timeout), counter-examples			

Tab. 1: NeuralSAT's features.

(FC), convolutional (CNN), residual (ResNet), batch normalization (BN) networks, etc. We also support mixtures of different types, e.g., VAEs which are large residual CNN-based networks. In addition to ReLU, NeuralSAT supports other major activation functions including sigmoid, tanh, and power.

Note that these are also supported by other DNN verification tools such as $\alpha\beta$ -CROWN though the LiRPA library [31]. However, it is straight-forward to extend NeuralSAT to support new layer or activation functions, by modifying the abstractions used in the T-solver to compute the approximation bounds of activation functions over different network layers. For example, VNN-COMP'24 has networks with "Exponential" and "Reciprocal" layers that were not supported by existing work and so we just extend our abstraction to compute the lower and upperbounds for these types of layers to allow NeuralSAT to verify them.

Standard Input and Output Formats NeuralSAT supports for inputs networks in the standard ONNX format [2] and properties in VNNLIB format [23]. The output of NeuralSAT is reported as unsat (property proved), sat (property disproved), or unknown and timeout (property cannot be proved). NeuralSAT also generates counterexamples for sat results in text format supported by VNN-COMPs.

Fully Automatic, but Configurable An important decision in designing NeuralSAT is to make it fully automatic and so that for end-users it "just works", perhaps even at the cost of some runtime. Users can simply apply NeuralSAT to check their networks and desired properties without any parameter configuration. For example, NeuralSAT runs on all VNN-COMP benchmarks with zero tuning. In contrast, top tools, such as $\alpha\beta$ -CROWN, require significant tuning to perform effectively (more details in §4).

However, NeuralSAT has many settings that can be configured by the users, such as the number of threads, number of restarts, timeout, etc. These options are useful for experts who want to explore different settings and optimize the performance of NeuralSAT for their specific problems.

Engineering Optimizations Despite the focus on theoretical contributions in research, engineering matters! NeuralSAT employs various engineering optimizations to improve performance. First, like most high performing DNN verifiers, NeuralSAT uses adversarial attack algorithms, e.g., derivative-free samplingbased [34] and gradient-based [17] methods, to quickly find counterexamples indicating property violation. Second, NeuralSAT preprocesses and applies heuristics that automatically select appropriate abstractions and algorithms based on input network structures and properties. For example, NeuralSAT focuses on splitting the input ranges for networks with low input dimension and splitting neurons for networks with many inputs (which are the majority of real-world and VNN-COMP DNNs).

What's New? In its latest version (after VNN-COMP'24), NeuralSAT has two new optimizations. First, for networks with large outputs (e.g., "Cifar100" networks with 100 outputs that often cause timeout due to heavy memory usage), NeuralSAT processes multiple output constraints at once and adjusts abstraction to compute approximations that are less precise, but consume significantly less memory. Second, for networks with small ReLU-based FC layers, NeuralSAT attempts to solve the problem using MILP solving directly before using the more expensive DPLL(T) search. §4 shows the improvements of these optimizations.

Commodity Hardware NeuralSAT heavily leverages the power of modern hardware, including multi-core CPUs and GPUs. The parallel search in NeuralSAT uses multi-threading, allowing multiple search subspaces to be processed in parallel. A large part of the theory solver in NeuralSAT is implemented to run on GPUs, which significantly speeds up the computation of neuron bounds. While leveraging hardware is common in DNN verification, the implementation is highly specific to the tool and requires careful engineering to achieve high performance. In VNN-COMP'23⁵, NeuralSAT was one of the fastest tools, often outperforming other top competitors.

Well-Tested NeuralSAT has been rigorously tested on a wide-range of benchmarks, including those in VNN-COMPs and many more. In fact, the benchmarks in VNN-COMP are often easy for NeuralSAT, and we actively seek out more challenging benchmarks to test the tool's capabilities, through our own benchmark generation research [30,29] and collaborations with other researchers and industry partners.

Active Development NeuralSAT is actively maintained with frequent updates. If the tool does not support a specific problem or benchmark, users are encouraged to open an issue on the project's GitHub page, and the team will strive to provide assistance (though in practice people often send emails instead of open Github issues). While the development version of NeuralSAT is quite usable, we aim to release stable versions approximately every 6 months.

 $^{^5}$ VNN-COMP'24 no longer measures verification runtime and instead uses timeout.

Fig. 2: VNN-COMP'24 updated results [5].

Extensibility As mentioned, NeuralSAT has many optimizations, and their addition was facilitated by the use of DPLL(T). The DPLL(T) framework in NeuralSAT is modular and extensible, consisting of a small core search algorithm and allows users to: add new decision or restart heuristics for DPLL, add new adversarial attacks in preprocessing, or extend the T-solver with additional abstraction or optimizations for DNN analysis. For example, the neuron stabilization optimization described in §2.2 is an independent function with fewer than 100 SLOCs and integrated via a hook method call into the core DPLL search. Similarly, heuristics are implemented as independent functions and can be easily replaced or extended (e.g., in current implementation decisions and restarts are less than 50 SLOC). NeuralSAT also uses the Gurobi LP solver as a black box and thus can switch to different solvers, e.g, Xpress [10], dReal [8].

4 Evaluation

4.1 VNN-COMP'24 Results

Fig. 2 summarizes the results of VNN-COMP'24 [5]. The table in the Fig. corresponds to Tab. 35 in Apdx. B of [5] and presents the overall scores and rankings of the tools. The cactus plot corresponds Fig. 29 in Apdx. B of [5] and shows tool performance on all benchmark instances. In summary, NeuralSAT₂₄ ranks 2nd overall, behind $\alpha\beta$ -CROWN and ahead of PyRAT.

4.2 New Results

We present the results of the latest version of NeuralSAT. We also compare it with NeuralSAT₂₄ and the latest version of $\alpha\beta$ -CROWN⁶. As mentioned in §3, the main updates are better handling of networks with large outputs and using MILP solving. We also compare NeuralSAT with $\alpha\beta$ -CROWN's default configuration, $\alpha\beta$ -CROWN_{default}, to show that NeuralSAT is competitive without any parameter tuning.

 $^{^{6}}$ https://github.com/Verified-Intelligence/alpha-beta-CROWN_vnncomp2024/commit/201f7401b3d8dbaddeda179939a8dc1615f8214a

Setup We reuse benchmarks and scripts for tool installation, execution, and scoring from VNN-COMP'24 [5]. In total there are 340 networks (ranging from 0.2K to 68M parameters) and 2058 properties. For, $\alpha\beta$ -CROWN_{default}, we run the script provided for $\alpha\beta$ -CROWN without a specific configuration (YAML) file and therefore uses its default settings. Details on the benchmarks and scoring system are available in [5] and Github repo⁷.

Our experiments were run on a Linux machine with an AMD Threadripper 64-core 4.2 GHz CPU, 128 GB RAM, and an NVIDIA GeForce RTX 4090 GPU with 24 GB VRAM. Because VNN-COMP'24 used Amazon AWS instances which are different than our machine, we experimented with timeouts and settled on 500 seconds per instance which allowed the verifiers to achieve similar scoring performance as in VNN-COMP'24. All considered tools leverage multiprocessing and GPU processing.

Results Tab. 2 shows the results. We report the Rank (#) and % is the percentage of solved problems over all problem instances of the corresponding benchmark. The last two columns break down the number of problems each verifier was able to verify and falsify. For example, for ACAS Xu, all tools other than $\alpha\beta$ -CROWN_{default} were able to verify all 186 problems (139 + 47), and $\alpha\beta$ -CROWN_{default} was only able to solve 113 problems (78 + 35), which is 60.8% of the total problems.

Overall, $\alpha\beta$ -CROWN ranks 1st, followed closely by NeuralSAT in 2nd, NeuralSAT₂₄ in 3rd, and $\alpha\beta$ -CROWN_{default} last. For NeuralSAT and $\alpha\beta$ -CROWN, the results are very close, with NeuralSAT verifying two fewer problems than $\alpha\beta$ -CROWN (1296 vs. 1298) and falsifying one fewer problem (981 vs. 982). NeuralSAT, with two new optimizations mentioned in §3, has similar performance on most benchmarks and outperforms NeuralSAT₂₄ on the remaining ones, with the most significant improvements in "Cifar100" and "Tiny ImageNet" (due to large output optimization) and "Safe NLP" (due to MILP solving).

The results show a significant performance disparity between $\alpha\beta$ -CROWN_{default} and $\alpha\beta$ -CROWN, with the latter having fine-tuned 10 parameters, on average, to optimize its performance for different benchmarks⁸. In contrast, NeuralSAT made no parameter adjustment for any benchmarks, highlighting its ease of use and potential for better performance in unseen benchmarks.

5 Related Work

The literature on DNN verification is rich and rapidly evolving (cf. [26,16]). Here we focus on tools competing in VNN-COMP'24 [5] because they are typically the state of the art and combine multiple effective DNN verification techniques.

Tab. 2: Results over VNN-COMP'24 Benchmarks

Several tools, including NeuralSAT, belong to the Branch-and-Bound (BaB) approach, which refines bounds computed for subproblems and then splits, or branches, them into subproblems that are solved separately. $\alpha\beta$ -CROWN combines GPU-accelerated linear bound propagation with advanced BaB techniques, such as cutting planes and neuron splitting, to scale to large networks. Marabou [28] (the successor of the popular Reluplex work [14]) encodes verification as constraint problems and uses parallelized split-and-conquer techniques for efficiency. nnenum [3] uses hidden BaB with star sets and several types of zonotope abstractions and focuses strictly on ReLU networks.

Other tools use reachability analysis, which overapproximates reachable states to verify properties. CORA [1] employs zonotopes for non-convex enclosures for open-loop and closed-loop verification in control systems. NeVer2 [7] focuses on ReLU-based feedforward networks by using an abstraction-refinement algorithm with symbolic bounds propagation. PyRAT [19] uses abstract interpretation with many domains including intervals, zonotopes, and polyhedra to compute sound overapproximations of reachable states to verify safe and robustness properties. NNV [25] focuses on verifying network-based control systems by integrating the star-set domain [24] with iteratively refinement for precise reachability analysis.

NeuralSAT achieves BaB through its DPLL(T) framework, which provides a strong algorithmic foundation and the flexibility to explore new heuristics and optimizations. NeuralSAT also delivers competitive performance out-of-thebox-an advantage over tools that require significant parameter tuning for good performance.

6 Conclusion and Future Work

NeuralSAT has quickly evolved into a leading performer in DNN verification, achieving similar performance to established competitors like $\alpha\beta$ -CROWN. By adopting modular and extensible designs, parallel DPLL(T) search, and advanced optimizations, NeuralSAT performs competitively across a diverse set of benchmarks, demonstrating its robustness and scalability. Its out-of-the-box usability, combined with its potential for further optimization and customization, make it an attractive choice for both researchers and practitioners.

Maintaining competitiveness in the world of rapid advancements requires continuous innovation in both algorithmic research and engineering advancements. We are exploring both algorithmic research, such as compositional reasoning [18,22], which decomposes large verification to more manageable subproblems, and decision heuristics from DPLL, such as VMTF (Variable Moveto-Front) [4], which prioritize variables involved in learned conflict clauses to improve search efficiency, and engineering improvements, such as enhancing parallelization and supporting multi-GPU hardware acceleration.
